Abstract

In this paper, we give two explicit constructions of extractors, both of which work for a source of any min-entropy on strings of length n. The first extracts any constant fraction of the min-entropy using $O(\log^2 n)$ additional random bits. The second extracts all the min-entropy using $O(\log^3 n)$ additional random bits. Both constructions use fewer truly random bits than any previous construction which works for all min-entropies and extracts a constant fraction of the min-entropy.

The extractors are obtained by observing that a weaker notion of "combinatorial design" suffices for the Nisan–Wigderson pseudorandom generator [NW94], which underlies the recent extractor of Trevisan [Tre98]. We give near-optimal constructions of such "weak designs" which achieve much better parameters than possible with the notion of designs used by Nisan–Wigderson and Trevisan.

1 Introduction

Roughly speaking, an extractor is a function which extracts truly random bits from a weakly random source, using a small number of additional random bits as a catalyst. A large body of work has focused on giving explicit constructions of extractors, as such constructions have a number of applications. A recent breakthrough was made by Luca Trevisan [Tre98], who discovered that the Nisan–Wigderson pseudorandom generator [NW94], previously only used in a computational setting, could be used to construct extractors. Trevisan's extractor improves on most previous constructions and is optimal for certain settings of the parameters. However, when one wants to extract all (or most) of the randomness from the weakly random source, Trevisan's extractor performs poorly, in that a large number of truly random "catalyst" bits are needed. In this paper, we give an extractor which extracts *all* of the randomness from the weakly random source using fewer truly random bits than any previous construction. This is accomplished by improving the combinatorial construction underlying the Nisan–Wigderson generator used in Trevisan's construction. Applying a construction of Wigderson and Zuckerman [WZ95], we also obtain improved expanders.

Extractors. A distribution X on $\{0,1\}^n$ is said to have *min-entropy* k if for all $x \in \{0,1\}^n$, $\Pr[X = x] \leq 2^{-k}$. Think of this as saying that X has "k bits of randomness." A function $\text{EXT}: \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is called an (k,ε)-*extractor* if for every distribution X on $\{0,1\}^n$ of min-entropy k, the induced distribution $\text{EXT}(X, U_d)$ on $\{0,1\}^m$ has statistical difference at most ε from uniform (where U_d is the uniform distribution on $\{0,1\}^d$). In other words, EXT extracts m (almost) truly random bits from a source with k bits of hidden randomness using d additional random bits as a catalyst. The goal is to explicitly construct extractors which minimize d (ideally, $d = O(\log(n/\varepsilon))$) while m is as close to k as possible.[1] *Dispersers* are the analogue of extractors for one-sided error; instead of inducing the uniform distribution, they simply hit all but a ε fraction of points in $\{0,1\}^m$.

[1] Actually, since the extractor is fed d truly random bits in addition to the k bits of hidden randomness, one can hope to have m be close to $k + d$. This will be discussed in more detail under the heading "Entropy loss."

Previous work. Dispersers were first defined by Sipser [Sip88] and extractors were first defined by Nisan and Zuckerman [NZ96]. Much of the motivation for research on extractors comes from work done on "somewhat random sources" [SV86, CG88, Vaz87b, VV85, Vaz84, Vaz87a]. There have been a number of papers giving explicit constructions of dispersers and extractors, with a steady improvement in the parameters [Zuc96, NZ96, WZ95, GW97, SZ98, SSZ98, NT98, TS98, Tre98]. Most of the work on extractors is based on techniques such as k-wise independence, the Leftover hash lemma [ILL89], and various forms of composition. A new approach to constructing extractors was recently initiated by Trevisan [Tre98], who discovered that the Nisan–Wigderson pseudorandom generator [NW94] could be used to construct extractors.

Explicit constructions of extractors and dispersers have a wide variety of applications, including simulating randomized algorithms with weak random sources [Zuc96]; constructing oblivious samplers [Zuc97]; constructive leader election [Zuc97]; randomness efficient error-reduction in randomized algorithms and interactive proofs [Zuc97]; explicit constructions of expander graphs, superconcentrators, and sorting networks [WZ95]; hardness of approximation [Zuc96]; pseudorandom generators for space-bounded computation [NZ96]; and other problems in complexity theory [Sip88, GZ97, ACR97].

For a detailed survey of previous work on extractors and their applications, see [NT98].

Our results. In this paper, we construct two extractors:

Theorem 1 *For every n, k, m, and ε, such that $m \leq k \leq n$, there are explicit (k, ε)-extractors* $\text{EXT}: \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ *with*

1. $d = O\left(\frac{\log^2(n/\varepsilon)}{\log(k/m)}\right)$
2. $d = O\left(\log^2(n/\varepsilon)\log(1/\gamma)\right)$, *where* $1+\gamma = k/(m-1)$, *and* $1/m \leq \gamma < 1/2$.

In particular, using the first extractor with k/m constant, we can extract any constant fraction of the source min-entropy using $O(\log^2 n)$ additional random bits, and, using the second extractor with $k = m$, we can extract all of the source min-entropy using $O((\log^2 n)(\log k))$ additional random bits. A comparison of these extractors with the best previous constructions is given in Figure 1. Our second extractor directly improves that of Ta-Shma [NT98], in that ours uses $O((\log^2 n)(\log k)) \leq O(\log^3 n)$ truly random bits in comparison to a polynomial of unspecified (and presumably large) degree in $\log n$. Both of our extractors use more truly random bits than the extractors of [Zuc97, Tre98] and the disperser of [TS98], but our extractors have the advantage that they work for any min-entropy (unlike [Zuc97]) and extract all (or a constant fraction) of the min-entropy (unlike [TS98, Tre98]). The disadvantage of the extractors of [GW97] described in Figure 1 is that they only use a small number of truly random bits when the source min-entropy k is very close to the input length n (e.g., $k = n - \text{polylog}(n)$), whereas ours uses $O(\log^3 n)$ random bits for any min-entropy. There are also extractors given in [GW97, SZ98] which extract all of the min-entropy, but these use a small number of truly random bits only when the source min-entropy is very small (e.g., $k = \text{polylog}(n)$), and these extractors are better discussed later in the context of entropy loss.

Plugging our second extractor into a construction of [WZ95] immediately yields the following expander graphs:

Corollary 2 *For every N and $K \leq N$, there is an explicitly constructible graph on N nodes with degree $(N/K) \cdot 2^{O((\log\log N)^2(\log\log K))}$ such that every two disjoint sets of vertices of size at least K have an edge between them.*

This degree compares with a degree bound of $(N/K) \cdot 2^{O(\text{poly}(\log\log N))}$ due to Ta-Shma [NT98]. Such expanders have applications to sorting and selecting in rounds, constructing depth 2 superconcentrators, and constructing non-blocking networks [Pip87, AKSS89, WZ95].

The Trevisan extractor. The main tool in the Trevisan extractor is the Nisan–Wigderson generator [NW94], which builds a pseudorandom generator out of any predicate P such that the security of the pseudorandom generator is closely related to how hard P is to compute (on average). Let $\mathcal{S} = (S_1, \ldots, S_m)$ be a collection of subsets of $[d]$ each of size ℓ, and let $P: \{0,1\}^\ell \to \{0,1\}$ be any predicate. For a string

[GW97]	any k	$m = k$	$d = O(n - k + \log(1/\varepsilon))$	extractor
[Zuc97]	$k = \Omega(n)$	$m = (1-\alpha)k$	$d = O(\log n)$	extractor
[NT98]	any k	$m = k$	$d = \text{polylog}(n)$	extractor
[TS98]	any k	$m = k^{1-o(1)}$	$d = O(\log n)$	disperser
[Tre98]	$k = n^{\Omega(1)}$	$m = k^{1-\alpha}$	$d = O(\log n)$	extractor
	any k	$m = k^{1-\alpha}$	$d = O((\log^2 n)/(\log k))$	extractor
ultimate goal	any k	$m = k$	$d = O(\log n)$	extractor
this paper	any k	$m = (1-\alpha)k$	$d = O(\log^2 n)$	extractor
	any k	$m = k$	$d = O((\log^2 n)(\log k))$	extractor

(Above, α is an arbitrarily small constant.)

Figure 1: Comparison with best previous constructions

$y \in \{0,1\}^d$, define $y|_{S_i}$ to be the string in $\{0,1\}^\ell$ obtained by projecting y onto the coordinates specified by S_i. Then the Nisan–Wigderson generator $\text{NW}_{\mathcal{S},P}\colon \{0,1\}^d \to \{0,1\}^m$ is defined as

$$\text{NW}_{\mathcal{S},P}(y) = P(y|_{S_1}) \cdots P(y|_{S_m}).$$

In the "indistinguishability proof" of [NW94], it is shown that for any function $D\colon \{0,1\}^m \to \{0,1\}$ which distinguishes the output of $\text{NW}_{\mathcal{S},P}(y)$ (for uniformly selected y) from the uniform distribution on $\{0,1\}^m$, there is a "small" circuit C (or procedure of small "description size") such that $C^D(\cdot)$ (*i.e.* , C with oracle access to D) approximates $P(\cdot)$ reasonably well. It is shown that the size of the C is related to $\max_{i \neq j} |S_i \cap S_j|$, so one should use a collection of sets in which this quantity is small, while trying to minimize the seed length d.

We now give a rough description of the Trevisan extractor $\text{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$. For a string $u \in \{0,1\}^n$, let $\overline{u} \in \{0,1\}^{\overline{n}}$ be an encoding of u in an error-correcting code (whose properties are unimportant in this informal description) and define $\ell = \log \overline{n}$. We view $\overline{u}$ as a boolean function $\overline{u}\colon \{0,1\}^\ell \to \{0,1\}$.

Then the extractor is simply

$$\text{Ext}_{\mathcal{S}}(u, y) = \text{NW}_{\mathcal{S},\overline{u}}(y) = \overline{u}(y|_{S_1}) \cdots \overline{u}(y|_{S_m}).$$

The analysis of this extractor in [Tre98] shows that the output of this extractor is close to uniform as long as the source min-entropy required is greater than the size of the circuit built in the security reduction of [NW94]. Hence, one needs to keep this circuit size small while minimizing the number d of truly random bits needed, which is equal to the seed length of the Nisan–Wigderson generator. Unfortunately, using $\max_{i \neq j} |S_i \cap S_j|$ as the measure of the circuit size as in [NW94, Tre98], one cannot make d much smaller than what is obtained in [Tre98].

The improvement. The improvements of this paper stem from the observation that actually $\max_i \sum_{j<i} 2^{|S_i \cap S_j|}$ is much better than $\max_{i \neq j} |S_i \cap S_j|$ as a measure of the size of the circuit built in the Nisan–Wigderson security reduction. So we are left with the problem of constructing set systems in which this quantity is small; we call such set systems *weak designs* (in contrast to *designs*, in which $\max_{i \neq j} |S_i \cap S_j|$ is bounded). We show that with weak designs, one can have d much smaller than is possible with the corresponding designs. The weak designs used in our first extractor are constructed using an application of the Probabilistic Method, which we then derandomize using the Method of Conditional Expectations (see [ASE92] and [MR95, Ch. 5]). We then apply a simple iteration to these first weak designs to obtain the weak designs used in our second extractor. We also prove a lower bound showing that our weak designs are near-optimal.

Entropy loss. Since a (k,ε)-extractor $\text{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is given k bits of hidden randomness in its first input and d truly random bits in its second input, one can actually hope for the output length

m to be almost $k+d$, rather than just k. The quantity $\Delta = k+d-m$ is therefore called the *entropy loss* of the extractor. Hence, in this language, the goal in constructing extractors is to simulataneously minimize both d and the entropy loss.

Nonconstructively, one can show that, for any n and $k \leq n$, there exist extractors $\text{EXT}_{n,k}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^{k+d-\Delta}$ with $d = \log(n-k) + O(1)$ and entropy loss $\Delta = 2\log(1/\varepsilon) + O(1)$, and these bounds on d and Δ are tight up to additive constants [RT97]. The explicit constructions, however, are still far from achieving these parameters. As for what is known, every entry in Figure 1 with $m = k$ has an entropy loss of d. For example, the extractor of [GW97] has an entropy loss of $O(n-k+\log(1/\varepsilon))$ (which is only interesting when k is very close to n) and the extractor of [NT98] has an entropy loss of $\text{polylog}\, n$. In addition, the "tiny families of hash functions" of [GW97, SZ98] give extractors with $d = O(k + \log n)$ and entropy loss $2\log(1/\varepsilon) + O(1)$; these are interesting when k is very small (e.g., $k = \text{polylog}\, n$)

A slight modification to our second extractor enables us to achieve logarithmic entropy loss:

Theorem 3 *For every n, k, and ε such that $k \leq n$, there is a (k,ε)-extractor $\text{EXT}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^{k+d-\Delta}$ with*

$$d = O\left(\left(\log^2(n/\varepsilon)\right)(\log k)\right)$$

and entropy loss

$$\Delta = 3\log(k/\varepsilon) + O(1)$$

2 Preliminaries

In this section, we introduce some standard terminology and notation used throughout the paper. log indicates the logarithm base 2 and ln denotes the natural logarithm. If X is a probability distribution on a finite set, we write $x \leftarrow X$ to indicate that x is selected according to X. Two distributions X and Y on a set S are said to have *statistical difference* (or *variation distance*) ε if

$$\max_D |\Pr[D(X)=1] - \Pr[D(Y)=1]| = \varepsilon,$$

where the maximum is taken over all functions ("distinguishers") $D\colon \{0,1\}^m \to \{0,1\}$. A distribution X is said to have *min-entropy* k if for all x, $\Pr[X=x] \leq 2^{-k}$. It is useful to think of distributions of min-entropy k as being uniform over a subset of the domain of size 2^k.

We write U_j for the uniform distribution on strings of length j. A function $\text{EXT}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a (k,ε)-*extractor* if for every distribution X of min-entropy k, $\text{EXT}(X, U_d)$ has statistical difference at most ε from U_m. In other words, EXT extracts m (almost) truly random bits from a source with k bits of hidden randomness using d additional random bits as a catalyst. We say that a family of extractors $\{\text{EXT}_i\colon \{0,1\}^{n_i} \times \{0,1\}^{d_i} \to \{0,1\}^{m_i}\}_{i \in I}$ is *explicit* if EXT_i can be evaluated in time $\text{poly}(n_i, d_i)$.

3 Combinatorial designs

The combinatorial construction underlying the Nisan–Wigderson generator are combinatorial designs.

Definition 4 ([NW94]) [2] *A family of sets $S_1, \ldots, S_m \subset [d]$ is an* (ℓ,ρ)-design *if*

1. *For all i, $|S_i| = \ell$.*
2. *For all $i \neq j$, $|S_i \cap S_j| \leq \log \rho$.*

[2] There is a somewhat related notion in the combinatorics literature known as a *2-design* (see, e.g. [AK92]). In 2-designs, strong additional regularity requirements are imposed (such as all the pairwise intersections being *exactly* the same size and all points being contained in the same number of sets). These additional requirements are irrelevant in our applications.

Motivation. In Trevisan's extractor, the parameters of a design correspond to the parameters of the extractor as follows:

$$\begin{aligned} \text{source min-entropy} &\approx \rho m \\ \text{output length} &= m \\ \text{input length} &= 2^{\Theta(\ell)} \\ \text{additional randomness} &= d \end{aligned}$$

Hence, our goal in constructing designs is to minimize d given parameters m, ℓ, and ρ (such that $\rho > 1$). Notice that $1/\rho$ is essentially the fraction of the source min-entropy that is extracted, so ideally ρ would be as close to 1 as possible.

One explicit construction of designs is given by the following:

Lemma 5 ([NW94, Tre98]) *For every m, ℓ, and $\rho > 1$, there exists an efficiently constructible (ℓ, ρ)-design $S_1, \ldots, S_m \subset [d]$ with*

$$d = \frac{\ell^2 m^{O(1/\log \rho)}}{\log \rho}.$$

Notice that the dependence on ρ is very poor. In particular, if we want to extract a constant fraction of the min-entropy, we need more than m^c truly random bits for some $c > 0$. This is unavoidable with the current definition of designs: if $\rho < 2$, then all the sets must be disjoint, so $d \geq m\ell$. In general, we have the following lower bound, obtained in joint work with Luca Trevisan and proved in Section 6:

Proposition 6 *If $S_1, \ldots, S_m \subset [d]$ is an (ℓ, ρ)-design, then*

$$d \geq m^{1/\log 2\rho} \cdot (\ell - \log \rho)$$

The improvements of this paper stem from the observation that actually a weaker form of design suffices for the Nisan–Wigderson generator and the construction of extractors:

Definition 7 *A family of sets $S_1, \ldots, S_m \subset [d]$ is a* weak (ℓ, ρ)-design *if*

1. *For all i, $|S_i| = \ell$.*
2. *For all i,*
$$\sum_{j<i} 2^{|S_i \cap S_j|} \leq \rho \cdot (m-1).$$

We will show that the parameters of a weak design correspond to the parameters of our extractors in the same way that designs corresponded to the parameters of Trevisan's extractor. Notice that every (ℓ, ρ)-design is a weak (ℓ, ρ)-design. But one can, for many settings of m, ℓ, and ρ achieve weak (ℓ, ρ)-designs $S_1, \ldots, S_m \subset [d]$ with much smaller values of d than possible with (ℓ, ρ)-designs. Indeed, we will prove the following in Section 5 using a probabilistic argument:

Lemma 8 *For every $\ell, m \in \mathbb{N}$ and $\rho > 1$, there exists a weak (ℓ, ρ)-design $S_1, \ldots, S_m \subset [d]$ with*

$$d = \left\lceil \frac{\ell}{\ln \rho} \right\rceil \cdot \ell.$$

Moreover, such a family can be found in time $\mathrm{poly}(m, d)$.

This is already much better than what is given by Lemma 5; for constant ρ, d is $O(\ell^2)$ instead of $\ell^2 m^c$. However, as ρ gets very close to 1, d gets very large. Specifically, if $\rho = 1 + \gamma$ for small γ, then the above gives $d = O(\ell^2/\gamma)$. To improve this, we notice that the proof of Lemma 8 does not take advantage of the fact that there are fewer terms in $\sum_{j<i} 2^{|S_i \cap S_j|}$ when i is small; indeed the proof actually shows how to

obtain $\sum_{j<i} 2^{|S_i \cap S_j|} < \rho \cdot (i-1)$ with the same d.[3] Since we only need a bound of $\rho \cdot (m-1)$ for all i, this suggests that we should "pack" more sets in the beginning. This packing is accomplished by iterating the construction of Lemma 8 (directly inspired by the iteration of Wigderson and Zuckerman [WZ95] on extractors), and yields the following improvement.

Lemma 9 *For every $\ell, m \in \mathbb{N}$ and $3/m \leq \gamma < 1/2$, there exists a weak $(m, \ell, 1+\gamma, d)$-design with*

$$d = O\left(\ell^2 \log \frac{1}{\gamma}\right).$$

Moreover, such a family can be found in time $\mathrm{poly}(m, d)$.

In particular, we can take $\gamma = \Theta(1/m)$ and extract essentially all of the entropy of the source using $d = O(\ell^2 \log m)$ truly random bits. Lemma 9 will be proven in Section 5.

For extractors which use only $O(\log n)$ truly random bits, where n is the input length, one would need $d = O(\ell)$. However, one cannot hope to do better than $\Omega(\ell^2)$ using the current analysis with weak designs. Indeed, the following proposition shows that our weak designs are optimal up to the $\log(1/\gamma)$ factor in our second construction.

Proposition 10 *For every (ℓ, ρ)-weak design $S_1, \ldots, S_m \subset [d]$,*

$$d \geq \min\left(\frac{\ell^2}{2 \log 2\rho}, \frac{m\ell}{2}\right)$$

Notice that $d = m\ell$ can be trivially achieved having all the sets disjoint and that $\log 2\rho$ approaches 1 as ρ approaches 1, so the lower bound for $\rho \approx 1$ is essentially $\Omega(\ell^2)$.

4 The extractor

In this section, we describe the Trevisan extractor and analyze its performance when used with our weak designs. The description of the extractor follows [Tre98] very closely. The main tool in the Trevisan extractor is the Nisan–Wigderson generator [NW94]. Let $\mathcal{S} = (S_1, \ldots, S_m)$ be a collection of subsets of $[d]$ of size ℓ, and let $P\colon \{0,1\}^\ell \to \{0,1\}$ be any boolean function. For a string $y \in \{0,1\}^d$, define $y|_{S_i}$ to be the string in $\{0,1\}^\ell$ obtained by projecting y onto the coordinates specified by S_i. Then the Nisan–Wigderson generator $\mathrm{NW}_{\mathcal{S},P}$ is defined as

$$\mathrm{NW}_{\mathcal{S},P}(y) = P(y|_{S_1}) \cdots P(y|_{S_m}).$$

In addition to the Nisan–Wigderson generator, the Trevisan extractor makes use of error-correcting codes:

Lemma 11 (Error-correcting codes) *For every n and δ there is a code $\mathrm{EC}_{n,\delta}\colon \{0,1\}^n \to \{0,1\}^{\overline{n}}$ where $\overline{n} = \mathrm{poly}(n, 1/\delta)$ such that every Hamming ball of relative radius $1/2 - \delta$ in $\{0,1\}^{\overline{n}}$ contains at most $1/\delta^2$ codewords. Furthermore, $\mathrm{EC}_{n,\delta}$ can be evaluated in time $\mathrm{poly}(n, 1/\delta)$ and $\overline{n}$ can be assumed to be a power of 2.*

We will actually use a stronger property of such error-correcting codes:

Proposition 12 *Let $\mathrm{EC}_{n,\delta}$ be any family of codes such that every Hamming ball of relative radius $1/2 - \delta$ contains fewer than B codewords and $\ln B \leq \delta^2 \cdot \overline{n}$. Then, for sufficiently small δ, every ℓ_1-ball of relative radius $1/2 - 2\delta$ in $[0,1]^{\overline{n}} \subset \mathbb{R}^{\overline{n}}$ contains at most B codewords. In other words, for every real vector $v \in [0,1]^{\overline{n}}$,*

$$\#\left\{ u \;\middle|\; \frac{1}{\overline{n}} \sum_{i=1}^{\overline{n}} |\mathrm{EC}(u)_i - v_i| < \frac{1}{2} - 2\delta \right\} < B$$

[3] In fact it is *necessary* that $d = \Omega(\ell^2 / \log \rho)$ if $\sum_{j<i} 2^{|S_i \cap S_j|} < \rho \cdot (i-1)$ for all i. See the remark after the proof of Proposition 10.

Since we may assume that $\overline{n} \geq \delta^{-2} \ln \delta^{-2}$ in Lemma 11, Proposition 12 applies to those codes with $B = 1/\delta^2$. The proof of Proposition 12 was obtained with the help of Madhu Sudan.

Proof: Suppose not, *i.e.* there are at least B codewords in an ℓ_1-ball of radius $1/2 - 2\delta$ around some real vector v. Then, consider a vector $w \in \{0,1\}^{\overline{n}}$ obtained by randomly rounding v. That is, let $w_i = 1$ with probability v_i for every i independently. Now consider any codeword $\overline{u}$ within ℓ_1-distance $1/2 - 2\delta$ of v. The Hamming distance between $\overline{u}$ and w has expectation $\|\overline{u} - v\|_1$ and is the sum of $\overline{n}$ i.i.d. $[0,1]$-valued random variables. By the Hoeffding inequality, the probability that the Hamming distance between $\overline{u}$ and w exceeds $\|\overline{u} - v\|_1 + \delta$ is at most $\exp(-2\overline{n}\delta^2)) = 1/|B|^2$. Hence, the probability that there are fewer than B codewords within Hamming distance $1/2 - \delta$ around w is at most $1/|B|$. Thus, there exists a w with at least B codewords within Hamming distance $1/2 - \delta$ contradicting the property of the error-correcting code. ■

We can now describe the Trevisan extractor, which takes as parameters n, m, k, and ε, where $m \leq n \leq k$. Let EC: $\{0,1\}^n \to \{0,1\}^{\overline{n}}$ be as in Lemma 12, with $\delta = \varepsilon/4m$ and define $\ell = \log \overline{n} = O(\log n/\varepsilon)$. For $u \in \{0,1\}^n$, we view $\mathrm{EC}(u)$ as a boolean function $\overline{u}$: $\{0,1\}^\ell \to \{0,1\}$.

Let $\mathcal{S} = (S_1, \ldots, S_m)$ be a collection of subsets of $[d]$ (for some d) such that $|S_i| = \ell$ for each i. (How $\mathcal{S}$ is selected will crucially affect the performance of the extractor; we will later choose it to be one of our weak designs.)

Then the extractor $\mathrm{EXT}_{\mathcal{S}}$: $\{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is defined as

$$\mathrm{EXT}_{\mathcal{S}}(u, y) = \mathrm{NW}_{\mathcal{S},\overline{u}}(y) = \overline{u}(y|_{S_1}) \cdots \overline{u}(y|_{S_m}).$$

We will now analyze this extractor. The following Lemma is implicit in [NW94] and is more explicitly shown in [Tre98]. It shows how, from any function D which distinguishes the output of $\mathrm{NW}_{\mathcal{S},P}$ from uniform, one can obtain a (randomized) "program" which, using D as an oracle, predicts P with noticeable advantage. This lemma shows that this "program" can be taken to be of a very simple form, which will allow us to bound its complexity later on. The only modification we need to the proofs of [NW94, Tre98] is that we do not use an averaging argument to fix the "random part" of the hybrids in the "hybrid argument"; rather, we keep these random.

Lemma 13 *Let P: $\{0,1\}^\ell \to \{0,1\}$ be any predicate and let D: $\{0,1\}^m \to \{0,1\}$ be any "distinguisher" such that*

$$\Pr_r [D(r) = 1] - \Pr_y [D(\mathrm{NW}_{\mathcal{S},P}(y)) = 1] > \varepsilon,$$

where r is selected uniformly from $\{0,1\}^m$ and y from $\{0,1\}^d$. Then there exists a there exists an $i \leq m$ and functions $P_1, \ldots, P_i$ from $\{0,1\}^\ell$ to $\{0,1\}$

1. *$\Pr_{x,b,r} [D(P_1(x), \ldots, P_{i-1}(x), b, r) \oplus b = P(x)] > \frac{1}{2} + \frac{\varepsilon}{m}$, where x is selected uniformly from $\{0,1\}^\ell$, b from $\{0,1\}$, and r from $\{0,1\}^{m-i}$.*
2. *Each P_j depends on only $|S_i \cap S_j|$ bits of x (where these bit positions depend only on $\mathcal{S}$ and i, but not on P or D)*

Proof sketch: We can expand the hypothesis of Lemma 13 as

$$\Pr_{r_1 \cdots r_m} [D(r_1 \cdots r_m) = 1] - \Pr_y [D(P(y|_{S_1}) \cdots P(y|_{S_m})) = 1] > \varepsilon,$$

where $r_1, \ldots, r_m$ are uniformly and independently selected bits and y is uniformly selected from $\{0,1\}^d$. By the "hybrid argument" of [GM84] (cf. [Gol95, Sec. 3.2.3]), there is an i such that

$$\Pr_{y, r_i \cdots r_m} \left[D\left(P(y|_{S_1}) \cdots P(y|_{S_{i-1}}) r_i \cdots r_m\right) = 1\right] - \Pr_{y, r_{i+1} \cdots r_m} [D(P(y|_{S_1}) \cdots P(y|_{S_i}) r_{i+1} \cdots r_m) = 1] > \varepsilon/m$$

Now, renaming r_i as b and using the standard transformation from distinguishers to predictors [Yao82] (cf. [Gol98, Sec. 3.3.3]), we see that

$$\Pr_{y, b, r_{i+1} \cdots r_m} \left[D\left(P(y|_{S_1}) \cdots P(y|_{S_{i-1}}) b r_{i+1} \cdots r_m\right) \oplus b = P(y|_{S_i})\right] > \frac{1}{2} + \frac{\varepsilon}{m}$$

Using an averaging argument we can fix all the bits of y outside S_i while preserving the prediction advantage. Renaming y_{S_i} as x, we now observe that x varies uniformly over $\{0,1\}^\ell$ while $P(y|_{S_j})$ for $j \neq i$ is now a function P_j of x that depends on only $|S_i \cap S_j|$ bits of x. So, we have

$$\Pr_{x,b,r_{i+1}\cdots r_m}[D(P_1(x)\cdots P_{i-1}(x) b r_{i+1}\cdots r_m) \oplus b = P(x)] > \frac{1}{2} + \frac{\varepsilon}{m},$$

as desired. □

Now we use a counting argument to bound the complexity (or "description size") of the "program" above and illustrate the connection with weak designs:

Lemma 14 *There is a set $\mathcal{F}$ of functions from $\{0,1\}^{\ell+1+m}$ to $\{0,1\}^m$ (depending only on $\mathcal{S}$) such that*

1. *For every predicate $P\colon \{0,1\}^\ell \to \{0,1\}$ and distinguisher $D\colon \{0,1\}^m \to \{0,1\}$ such that*

$$\Pr_r[D(r)=1] - \Pr_y[D(\mathrm{NW}_{\mathcal{S},P}(y))=1] > \varepsilon,$$

   there exists a function $f \in \mathcal{F}$ such that

$$\Pr_{x,b,r}[D(f(x,b,r)) \oplus b = P(x)] > \frac{1}{2} + \frac{\varepsilon}{m},$$

   where x is selected uniformly from $\{0,1\}^\ell$, b from $\{0,1\}$, and r from $\{0,1\}^m$.

2. $\log|\mathcal{F}| \le \log m + \max_i\left(\sum_{j<i} 2^{|S_i\cap S_j|}\right)$.

3. *Each function in $\mathcal{F}$ can be computed by a circuit of size $O\left(\max_i\left(\sum_{j<i}|S_i\cap S_j|\cdot 2^{|S_i\cap S_j|}\right)\right)$.*[4]

We will not use Item 3 (the bound on circuit size) in the analysis of our extractor; we only use this for our quantitative improvement to the pseudorandom generators of [NW94] given in Section 8.

Proof: By Lemma 13, to meet Condition 1 it suffices to let $\mathcal{F}$ be the set of functions f of the form $(x,b,r) \mapsto (P_1(x), P_2(x), \ldots, P_{i-1}(x), b, r)$, where $P_j(x)$ depends only some set T_{ij} of bits of x, where $|T_{ij}| = |S_i \cap S_j|$. The number of bits it takes to represent i is $\log m$. Given i, the number of bits it takes to represent each P_j is $2^{|T_{ij}|} = 2^{|S_i\cap S_j|}$. So, the total number of bits it takes to represent a function in $\mathcal{F}$ is $\log m + \max_i \sum_{j<i} 2^{|S_i\cap S_j|}$, giving the desired bound on $\log|\mathcal{F}|$.

For the bound on circuit size, notice that the circuit size of f is simply the sum of the circuit sizes of the P_j's, and every function on k bits can be computed by a circuit of size $O(k2^k)$. ■

We now analyze the extractor $\mathrm{EXT}_{\mathcal{S}}$ when we take $\mathcal{S}$ to be a weak design. The argument follows the analysis of Trevisan's extractor in [Tre98] except that we use the more refined bounds on $|\mathcal{F}|$ given by Lemma 14.

Proposition 15 *If $\mathcal{S} = (S_1, \ldots, S_m)$ (with $S_i \subset [d]$) is a weak (ℓ,ρ)-design for $\rho = (k - 3\log(m/\varepsilon) - 5)/m$ (where c is a fixed constant), then $\mathrm{EXT}_{\mathcal{S}}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a (k,ε)-extractor.*

Proof: Let X be any distribution of min-entropy k. We need to show that the statistical difference between U_m and $\mathrm{EXT}(X, U_d)$ is at most ε. By the definition of statistical difference, this is equivalent to showing that, for every distinguisher $D\colon \{0,1\}^m \to \{0,1\}$,

$$\Pr_r[D(r)=1] - \Pr_{u\leftarrow X, y}[D(\mathrm{NW}_{\mathcal{S},\overline{u}}(y))=1] \le \varepsilon$$

[4] We measure circuit size by the number of *internal* gates, so, for example, the identity function has circuit size 0.

where r and y are selected uniformly from $\{0,1\}^m$ and $\{0,1\}^d$, respectively. (We have dropped the absolute value in the definition of statistical difference; this is without loss of generality since we may replace D by its binary complement.) So let $D\colon \{0,1\}^m \to \{0,1\}$ be any distinguisher and let $\mathcal{F}$ be as in Lemma 14, so $|\mathcal{F}| \leq m2^{\rho m}$. For every $f \in \mathcal{F}$, we obtain a function $\hat{f}\colon \{0,1\}^\ell \to [0,1]$ given by

$$\hat{f}(x) = \Pr_{b,r}[D(f(x,b,r)) \oplus b = 1].$$

Think of $D(f(x,b,r)) \oplus b$ as a randomized algorithm built out of D with input x and random coins (b,r). We can view each $\hat{f}$ as a vector $\hat{f} \in [0,1]^{\overline{n}}$. Notice that for a predicate $P\colon \{0,1\}^\ell \to \{0,1\}$ (which we can also view as a vector $P \in \{0,1\}^{\overline{n}}$), the ℓ_1-distance between $\hat{f}$ and P gives the probability that the randomized algorithm corresponding to f computes P incorrectly. That is,

$$|\hat{f} - P|_1 = \Pr_{b,r}[D(f(x,b,r)) \oplus b \neq P(x)].$$

Let B be the set of u for which there exists an $f \in \mathcal{F}$ such that $|\hat{f} - \overline{u}|_1 < 1/2 - \varepsilon/2m$. In other words, B is the set of "bad" u for which $\overline{u}$ can be approximated easily by one of these randomized algorithms $\hat{f}$. By the property of the error-correcting code given in Proposition 12, for each function $f \in \mathcal{F}$, there are at most $(4m/\varepsilon)^2$ strings $u \in \{0,1\}^n$ such that $|\hat{f} - \overline{u}|_1 < 1/2 - \varepsilon/2m$. By the union bound,

$$|B| \leq (4m/\varepsilon)^2 \cdot |\mathcal{F}| = (4m/\varepsilon)^2 \cdot 2^{\rho m}.$$

Since X has min-entropy k, each $u \in B$ has probability at most 2^{-k} of being selected from X, so

$$\begin{aligned}
\Pr_{u \leftarrow X}[u \in B] &\leq \left((4m/\varepsilon)^2 m 2^{\rho m}\right) \cdot 2^{-k} \\
&= \left((4m/\varepsilon)^2 m 2^{k - 3\log(m/\varepsilon) - 5}\right) \cdot 2^{-k} \\
&< \varepsilon/2
\end{aligned}$$

Now, by Lemma 14, if $u \notin B$, then

$$\Pr_r[D(r) = 1] - \Pr_y[D(\mathrm{NW}_{\mathcal{S},\overline{u}}(y)) = 1] < \varepsilon/2.$$

Thus,

$$\begin{aligned}
\Pr_r[D(r) = 1] - \Pr_{u \leftarrow X, y}[D(\mathrm{NW}_{\mathcal{S},\overline{u}}(y)) = 1] &= \mathop{\mathrm{E}}_{u \leftarrow X}\left[\Pr_r[D(r) = 1] - \Pr_y[D(\mathrm{NW}_{\mathcal{S},\overline{u}}(y)) = 1]\right] \\
&\leq \Pr_{u \leftarrow X}[u \in B] + \Pr_{u \leftarrow X}[u \notin B] \cdot \varepsilon/2 \\
&\leq \varepsilon/2 + \varepsilon/2 = \varepsilon.
\end{aligned}$$

■

Combining Proposition 15 with the weak designs given by Lemmas 8 and 9 essentially proves Theorem 1. The only technicality is that Proposition 15 does not allow us to take $\rho = k/m$ (or $k/(m-1)$) which is what we would need to deduce Theorem 1 directly. Instead, we lose $\Delta = 3\log(m/\varepsilon) + 5$ bits of the source entropy in Proposition 15. However, since Δ is so small, we can give our extractor Δ more truly random bits in its seed (increasing d by only a constant factor) which we just concatenate to the output to compensate for the loss. The details of this are given below.

Proof of Theorem 1: Let $\Delta = 3\log(m/\varepsilon)+5$. Let $k' = k-\Delta$, $m' = m-\Delta-3$, and $\rho = k'/m' > k/(m-1)$. For 1 or 2, apply Proposition 15 with the weak (ℓ,ρ)-design $S_1,\ldots,S_{m'} \subset [d']$ of Lemma 8 or Lemma 9, respectively. This gives an (k,ε)-extractor $\mathrm{Ext}\colon \{0,1\}^n \times \{0,1\}^{d'} \to \{0,1\}^{m'}$, with $d' = O\left(\frac{\log^2(n/\varepsilon)}{\log(k/m)}\right)$ or $d' = O(\log^2(n/\varepsilon)\log(1/\gamma))$, respectively. By using $\Delta + 3$ additional bits in the seed and simply concatenating these to the output, we obtain a (k,ε)-extractor $\mathrm{Ext}\colon \{0,1\}^n \times \{0,1\}^{d'+\Delta+3} \to \{0,1\}^m$, as desired.

(In applying Lemma 9, we need to make sure that $\rho < 3/2$, but if $\rho \geq 3/2$, we can use the weak design of Lemma 8 instead.) ■

Remark The stronger property of error-correcting codes given by Proposition 12 which corresponds to hardness against randomized algorithms could have been avoided by using an averaging argument to "fix" r and b in Lemma 13. If this is done in a straightforward manner, we would have to pay a price for these bits in the size of $\mathcal{F}$, as they would be needed to fully describe a function. The cost of these bits can be avoided, however, if we do the hybrid argument while we are still looking at the advantage of the distinguisher *averaged over the choice of* u; then these bits can be fixed independently of u and absorbed into the distinguisher *before* we make the counting argument which says that the distinguisher fails with probability at least $1-\varepsilon/2$ over the choice of $u \leftarrow X$. Doing the analysis this way eliminates the $\log m$ term in the bound on $\log|\mathcal{F}|$. However, the approach we have taken, advocated by Oded Goldreich, corresponds better to the intuition that one should not pay a price for r and b since they can be taken to be random.

5 Construction of weak designs

Proof of Lemma 8: Let ℓ, m, and ρ be given, and let $d = \lceil \ell / \ln \rho \rceil \cdot \ell$. We view $[d]$ as the disjoint union of ℓ blocks $B_1, \ldots, B_\ell$, each of size $\lceil \ell / \ln \rho \rceil$. We construct the sets $S_1, \ldots, S_m$ in sequence so that

1. Each set contains exactly one element from each block, and
2. $\sum_{j<i} 2^{|S_i \cap S_j|} \leq \rho \cdot (i-1)$.

Supppose we have $S_1, \ldots, S_{i-1} \subset [d]$ satisfying the above conditions. We prove that there exists a set S_i satisfying the required conditions using the Probabilistic Method [ASE92] (see also [MR95, Ch. 5]). Let $a_1, \ldots, a_\ell$ be uniformly and independently selected elements of $B_1, \ldots, B_\ell$, respectively, and let $S_i = \{a_1, \ldots, a_\ell\}$. We will argue that with nonzero probability, Condition 2 holds. Let $Y_{j,k}$ be the indicator random variable for whether $a_k \in S_j$, so $\Pr[Y_{j,k} = 1] = 1/|B_j| = 1/\lceil \ell / \ln \rho \rceil$. Notice that for a fixed j, the random variables $Y_{j,1}, \ldots, Y_{j,\ell}$ are independent.

$$\begin{aligned}
\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|}\right] &= \sum_{j<i} \mathrm{E}\left[2^{\sum_k Y_{j,k}}\right] \\
&= \sum_{j<i} \mathrm{E}\left[\prod_k 2^{Y_{j,k}}\right] \\
&= \sum_{j<i} \prod_k \mathrm{E}\left[2^{Y_{j,k}}\right] \\
&= (i-1) \cdot \left(1 + \frac{1}{\lceil \ell / \ln \rho \rceil}\right)^\ell \\
&\leq (i-1) \cdot \rho
\end{aligned}$$

Hence, with nonzero probability, Condition 2 holds, so a set S_i satisfying the requirements exists. However, we want to find such a set deterministically. This can be accomplished by a straightforward application of the Method of Conditional Expectations (see [ASE92] and [MR95, Ch. 5]). Details can be found in Appendix A. ■

Remark A perhaps more natural way to carry out the above probabilistic construction is to chose S_i uniformly from the set of all subsets of $[d]$ of size ℓ, rather than dividing $[d]$ into ℓ blocks. This gives essentially

the same bounds, but complicates the analysis because the elements of S_i are no longer independent. The cleaner approach in the above proof was suggested by David Zuckerman.

Proof of Lemma 9: For simplicity, assume that $1+\gamma = 1/(1-2^{-h})$ and $m = 2^q/(1+\gamma)$. Let $d_0 = \lceil \ell/\ln 2 \rceil \cdot \ell$ and let $d = h \cdot d_0 = O(\ell^2 \cdot \log(1+\gamma))$. We view $[d]$ as the disjoint union of h blocks $B_1, \ldots, B_h$ each of size d_0. For each $t \in [h]$, let $m_t = 2^{q-t}$ and $n_t = \sum_{s=1}^{t-1} m_s$, so $\sum_t m_t = m$.

Now we define our weak design $S_1, \ldots, S_m$. For each $t \in [h]$, we let $S_{n_t+1}, \ldots, S_{n_t+m_t} \subset B_t$ be a weak $(\ell, 2)$-design as given by Lemma 8. In other words, we take the ordered union of h weak $(\ell, 2)$-designs (consisting of $m_1, m_2, \ldots, m_h$ sets, respectively) using disjoint subsets of the universe for each. The number of sets is m, the size of the universe is d, and each set is of size ℓ, so we only need to check that for all $i \in [m]$, $\sum_{j<i} 2^{|S_i \cap S_j|} < \rho \cdot (m-1)$. For $i \in \{n_t+1, \ldots, n_t+m_t\}$, S_i is disjoint from any S_j for any $j \leq n_t$ and

$$\sum_{j=n_t+1}^{i-1} 2^{|S_i \cap S_j|} \leq 2 \cdot (m_t - 1).$$

since $S_{n_t+1}, \ldots, S_{n_t+m_t}$ is a weak $(\ell, 2)$-design.

Thus, we have

$$\begin{aligned} \sum_{j<i} 2^{|S_i \cap S_j|} &= \sum_{j=1}^{n_t} 2^{|S_i \cap S_j|} + \sum_{j=n_t+1}^{i-1} 2^{|S_i \cap S_j|} \\ &\leq n_t + 2 \cdot (m_t - 1) \\ &= 2^q - 2 < (1+\gamma)(m-1), \end{aligned}$$

as desired. ■

6 Lower bounds for designs

Proof of Proposition 6: Let $I = \max_{i \neq j} |S_i \cap S_j| \leq \log \rho$. For each $j = 1, \ldots, m$, let $,_j$ be the set of subsets of S_j of size $I+1$, so $|,_j| = \binom{\ell}{I+1}$. Let $, = \bigcup_j ,_j$. Notice that the sets $,_j$ are disjoint, because no two distinct sets S_i, S_j share more than I elements. Thus, $|,| = m \cdot \binom{\ell}{I+1}$. At the same time, $|,|$ consists of subsets of $[d]$ of size $I+1$, so $|,| \leq \binom{d}{I+1}$. So we have

$$m \cdot \binom{\ell}{I+1} \leq \binom{d}{I+1}.$$

Expanding the binomial coefficients and rearranging terms, we have

$$m \leq \left(\frac{d}{\ell}\right)\left(\frac{d-1}{\ell-1}\right)\cdots\left(\frac{d-I}{\ell-I}\right) \leq \left(\frac{d}{\ell-I}\right)^{I+1} \leq \left(\frac{d}{\ell-\log\rho}\right)^{\log 2\rho}$$

■

Proof of Proposition 10: We have

$$\begin{aligned} \rho &\geq \max_i \frac{1}{m-1} \sum_{j<i} 2^{|S_i \cap S_j|} \\ &\geq \frac{1}{m(m-1)} \sum_{i=1}^{m} \sum_{j<i} 2^{|S_i \cap S_j|} \end{aligned}$$

$$
\begin{aligned}
&= \frac{1}{2m(m-1)} \sum_{i \neq j} 2^{|S_i \cap S_j|} \\
&\geq \frac{1}{2} \left(2^{\frac{1}{m(m-1)} \sum_{i \neq j} |S_i \cap S_j|} \right)
\end{aligned}
$$

where the last inequality follows from Jensen's inequality. Thus,

$$
\log 2\rho > \frac{1}{m^2} \sum_{i \neq j} |S_i \cap S_j| \tag{1}
$$

Now, for $a \in [d]$, let $n_a = |\{i : a \in S_i\}|$. Then $\sum_a n_a = \sum_i |S_i| = m \cdot \ell$.

$$
\begin{aligned}
\sum_{i \neq j} |S_i \cap S_j| &= \sum_{a \in [d]} n_a (n_a - 1) \\
&= \sum_a n_a^2 - \sum_a n_a \\
&= \sum_a n_a^2 - m\ell \\
&\geq \frac{1}{d} \left(\sum_a n_a \right)^2 - m\ell \\
&= \frac{m^2 \ell^2}{d} - m\ell \\
&\geq \frac{m^2 \ell^2}{2d},
\end{aligned}
$$

unless $d \geq (m\ell)/2$. Putting this in Inequality 1, we have

$$
\log 2\rho > \frac{1}{m^2} \cdot \frac{m^2 \ell^2}{2d} = \frac{\ell^2}{2d}
$$

which proves the proposition. ■

Remark The above proof gives a stronger bound on d if we have a family of sets $S_1, \ldots, S_m$ such that for all i, $\sum_{j<i} 2^{|S_i \cap S_j|} < \rho \cdot (i-1)$ (e.g., the family of sets constructed in the proof of Lemma 8). If we have such a bound, then summing over i from 1 to m gives

$$
\rho \cdot \binom{m}{2} > \frac{1}{2} \sum_{i \neq j} 2^{|S_i \cap S_j|},
$$

and applying Jensen's inequality and taking logs as in the above proof gives

$$
\log \rho > \frac{1}{m^2} \sum_{i \neq j} |S_i \cap S_j|
$$

instead of Inequality 1. Following the rest of the proof without change, this shows that

$$
d \geq \min \left(\frac{\ell^2}{2 \log \rho}, \frac{m\ell}{2} \right).
$$

7 Achieving small entropy loss

Recall that the *entropy loss* of an extractor $\text{EXT}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is defined as $\Delta = k + d - m$, and we can hope for this to be as small as $2\log(1/\varepsilon) + O(1)$ with $d = \log(n-k) + O(1)$ [RT97].

In constructing our extractor $\text{EXT}_{\mathcal{S}}(u,y) = \text{NW}_{\mathcal{S},\overline{u}}(y)$, we "threw away" y after using it as a seed for the Nisan–Wigderson generator and hence the d bits of entropy carried by y were lost. However, the analysis of the Nisan–Wigderson generator actually shows that the quality of the generator is not affected if the seed is revealed. Thus, we define $\text{EXT}'_{\mathcal{S}}(u,y) = (y, \text{NW}_{\mathcal{S},\overline{u}}(y))$. Now all the analysis of EXT done in Section 4 actually applies to EXT' (in Lemmas 13 and 14, give the distinguisher D the seed y in addition to $\text{NW}_{\mathcal{S},\overline{u}}(y)$), and we obtain the following strengthening of Proposition 15:

Proposition 16 *If $\mathcal{S} = (S_1, \ldots, S_m)$ (with $S_i \subset [d]$) is a weak (ℓ,ρ)-design for $\rho = (k - 3\log(m/\varepsilon) - 5)/m$, then $\text{EXT}'_{\mathcal{S}}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^{m+d}$ is a (k,ε)-extractor.*

Combining Proposition 16 and Lemma 9 with $m = k - 1$ immediately gives Theorem 3. An additional additive factor of $\log m$ can be removed from the entropy loss by taking the alternative approach mentioned in the remark at the end of Section 4. Note that the trick of adding extra bits to the seed and concatenating these to the output, as we did in the proof of Theorem 1, does not help in reducing the entropy loss.

8 Better pseudorandom generators

Using alternative types of designs also gives some quantitative improvements in the construction of pseudorandom generators from hard predicates in [NW94]. From Lemma 14, we see that the relevant notion of design in the setting of circuit complexity-based pseudorandom generation is the following:

Definition 17 *A family of sets $S_1, \ldots, S_m \subset [d]$ is a* type 2 weak (ℓ,ρ)-design *if*

1. *For all i, $|S_i| = \ell$.*
2. *For all i,*
$$\sum_{j<i} |S_i \cap S_j| \cdot 2^{|S_i \cap S_j|} \le \rho \cdot (m-1).$$

Notice that it is meaningful to consider even values of ρ less than 1, since $|S_i \cap S_j| \cdot 2^{|S_i \cap S_j|}$ can be zero. Using a construction like the one in Lemma 8, we obtain

Lemma 18 *For every $\ell, m \in \mathbb{N}$ and $\rho > 0$, there exists a type 2 weak (ℓ,ρ)-design $S_1, \ldots, S_m \subset [d]$ with*

$$d = \begin{cases} O\left(\frac{\ell^2}{\ln \rho\ell}\right) & \text{if } \rho \ge \frac{6}{\ell} \\ O\left(\frac{\ell}{\rho}\right) & \text{if } \rho < \frac{6}{\ell} \end{cases}$$

Moreover, such a family can be found in time $\text{poly}(m,d)$.

The quantitative relation between pseudorandom generators and type 2 weak designs follows readily from Lemma 14:

Lemma 19 *Suppose $P\colon \{0,1\}^\ell \to \{0,1\}$ is a predicate such that no circuit of size s can compute P correctly on more than a fraction $\frac{1}{2} + \varepsilon$ of the inputs and suppose that $\mathcal{S} = (S_1, \ldots, S_m)$ where $S_i \subset [d]$ is a type 2 weak (ℓ,ρ)-design. Then no circuit of size $s - \rho m$ can distinguish $\text{NW}_{\mathcal{S},P}$ from uniform with advantage greater than $m\varepsilon$.*

Combining this and Lemma 18 with $\rho = 1$ and $s = 2m$, we obtain

Theorem 20 *Suppose* $P\colon \{0,1\}^\ell \to \{0,1\}$ *is a predicate such that that no circuit of size* $2m$ *can compute* P *correctly on more than a fraction* $\frac{1}{2} + \frac{\varepsilon}{m}$ *of the inputs. Then there is a generator* $G_{P,m}\colon \{0,1\}^{O(\ell^2/\log \ell)} \to \{0,1\}^m$ *computable in time* $\mathrm{poly}(m,\ell)$*, making* m *oracle calls to* P*, such that no circuit of size* m *can distinguish the output of* G *from uniform with advantage greater than* ε*.*

In other words, to obtain m bits which are pseudorandom against circuits of size m, we need only assume that there is a predicate which is hard against circuits of size $O(m)$. In contrast, the results of [NW94] always need to assume that the predicate is hard against circuits of size $m^{1+\epsilon}$ for some constant $\epsilon > 0$ (or else their generator will require a seed length that is polynomial in m instead of ℓ). In fact, if we instead take $\rho = 1/\ell$, we need only assume that the predicate is hard against circuits of size $(1 + 1/\ell) \cdot m$ (and the generator will have a seed length $O(\ell^2)$).

Acknowledgments

I am grateful to Luca Trevisan for sharing his novel insights into these problems with me. I acknowledge Oded Goldreich, Madhu Sudan, and David Zuckerman for several simplifications of the proofs in this paper and for helpful discussions. Further thanks to Oded Goldreich for valuable comments on the presentation.

A Derandomizing the proof of Lemma 8

In the analysis of the probabilistic choice of S_i, we showed that

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|}\right] \leq \rho \cdot (i-1)$$

By averaging, this implies that there exists an $\alpha_1 \in B_1$ such that

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \middle| a_1 = \alpha_1\right] \leq \rho \cdot (i-1) \tag{2}$$

So, assuming we can efficiently calculate the conditional expectation $\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \middle| a_1 = \alpha_1\right]$ for every $\alpha_1 \in B_1$, we can find the α_1 that makes Inequality 2 hold. Then, fixing such an α_1, another averaging argument implies that there exists an $\alpha_2 \in B_2$ such that

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \middle| a_1 = \alpha_1, a_2 = \alpha_2\right] \leq \rho \cdot (i-1) \tag{3}$$

Again, assuming that we can compute the appropriate conditional expectations, we can find an α_2 that makes Inequality 3 hold. Proceeding like this, we obtain $\alpha_1, \ldots, \alpha_\ell$ such that

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \middle| a_1 = \alpha_1, a_2 = \alpha_2, \ldots, a_\ell = \alpha_\ell\right] \leq \rho \cdot (i-1) \tag{4}$$

But now there is no more randomness left in the experiment, and Inequality 4 simply says that $\sum_{j<i} 2^{|S_i \cap S_j|} \leq \rho \cdot (i-1)$, for $S_i = \{\alpha_1, \ldots, \alpha_\ell\}$. To implement this algorithm for finding S_i, we need to be able to calculate the conditional expectation

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \middle| a_1 = \alpha_1, \ldots, a_i = \alpha_i\right],$$

for any i and $\alpha_1, \ldots, \alpha_i$. If we let $T = \{\alpha_1, \ldots, \alpha_i\}$, then a calculation like the one in the proof of Lemma 8 for the unconditional expectation shows

$$\mathrm{E}\left[\sum_{j<i} 2^{|S_i \cap S_j|} \,\middle|\, a_1 = \alpha_1, \ldots, a_i = \alpha_i\right] = \sum_{j<i} 2^{|T \cap S_j|} \left(1 + \frac{1}{\lceil \ell / \ln \rho \rceil}\right)^{\ell - i},$$

which can be easily computed.
